## Survival data

Persons enter the study at some date.

Persons exit at a later date, either dead or alive.

Observation:

Actual time span to death ("event")

or

Some time alive ("censoring")

## Examples of time-to-event measurements

- ▶ Time from diagnosis of cancer to death.
- ▶ Time from randomisation to death in a cancer clinical trial
- ▶ Time from HIV infection to AIDS.
- ▶ Time from marriage to 1st child birth.
- ▶ Time from marriage to divorce.
- ▶ Time to re-offending after being released from jail

## Survival after Cervix cancer

Year	Stage I			Stage II		
	<i>N</i>	<i>D</i>	<i>L</i>	<i>N</i>	<i>D</i>	<i>L</i>
1	110	5	5	234	24	3
2	100	7	7	207	27	11
3	86	7	7	169	31	9
4	72	3	8	129	17	7
5	61	0	7	105	7	13
6	54	2	10	85	6	6
7	42	3	6	73	5	6
8	33	0	5	62	3	10
9	28	0	4	49	2	13
10	24	1	8	34	4	6

Estimated risk in year 1 for Stage I women is  $5/107.5 = 0.0465$

Estimated 1 year survival is  $1 - 0.0465 = 0.9535$

Life table estimator.

## Survival function

Persons enter at time 0:

Date of birth, date of randomization, date of diagnosis.

How long do they survive?

Survival time  $T$  — a stochastic variable.

Distribution is characterized by the survival function:

$$\begin{aligned} S(t) &= P\{\text{survival at least till } t\} \\ &= P\{T > t\} = 1 - P\{T \leq t\} = 1 - F(t) \end{aligned}$$

$F(t)$  is the cumulative risk of death before time  $t$ .

Survival Multiple timescales Competing risks Bendix Carstensen Rates and Survival Life-table estimators Kaplan-Meier estimators The Cox-model Who needs the Cox-model anyway? Multiple time scales Competing risks 16/ 79

## Intensity / rate / hazard — same same

- ▶ The **intensity** or **hazard function**
- ▶ Probability of event in interval, relative to interval length:

$$\lambda(t) = P\{\text{event in } (t, t+h] \mid \text{alive at } t\} / h$$

- ▶ Characterizes the distribution of survival times as does  $f$  (density) or  $F$  (cumulative distribution).
- ▶ Theoretical counterpart of a(n empirical) **rate**.

Rates and Survival (surv-rate)

Survival Multiple timescales Competing risks Bendix Carstensen Rates and Survival Life-table estimators Kaplan-Meier estimators The Cox-model Who needs the Cox-model anyway? Multiple time scales Competing risks 12/ 79

## Statistical inference: Likelihood

Two things needed:

- ▶ **Data** — what did we actually observe  
Follow-up for each person:  
Entry time, exit time, exit status, covariates
- ▶ **Model** — how was data generated  
Rates as a function of time:  
Probability machinery that generated data

**Likelihood** is the probability of observing the **data**, assuming the **model** is correct.

**Maximum likelihood** estimation is choosing **parameters** of the model that makes the likelihood maximal.

Rates and Survival (surv-rate)

Survival Multiple timescales Competing risks Bendix Carstensen Rates and Survival Life-table estimators Kaplan-Meier estimators The Cox-model Who needs the Cox-model anyway? Multiple time scales Competing risks 17/ 79

## Survival and rate

Survival from rate — and vice versa;

$$S(t) = \exp\left(-\int_0^t \lambda(s) ds\right) \quad \lambda(t) = \frac{S'(t)}{S(t)}$$

Survival is a **cumulative** measure, the rate is an **instantaneous** measure.

**Note:** A cumulative measure requires an origin!

... it is always survival **since** some timepoint — here 0

Rates and Survival (surv-rate)

Survival Multiple timescales Competing risks Bendix Carstensen Rates and Survival Life-table estimators Kaplan-Meier estimators The Cox-model Who needs the Cox-model anyway? Multiple time scales Competing risks 13/ 79

## Likelihood from one person

- ▶ The likelihood from several empirical rates from one individual is a product of conditional probabilities:

$$P\{\text{event at } t_4 | t_0\} = P\{\text{survive } (t_0, t_1) \text{ alive at } t_0\} \times P\{\text{survive } (t_1, t_2) \text{ alive at } t_1\} \times P\{\text{survive } (t_2, t_3) \text{ alive at } t_2\} \times P\{\text{event at } t_4 \text{ alive at } t_3\}$$

- ▶ Log-likelihood from one individual is a sum of terms.
- ▶ Each term refers to one empirical rate  $(d, y)$  —  $y = t_i - t_{i-1}$  and mostly  $d = 0$ .
- ▶  $t_i$  is the timescale (covariate).

Rates and Survival (surv-rate)

Survival Multiple timescales Competing risks Bendix Carstensen Rates and Survival Life-table estimators Kaplan-Meier estimators The Cox-model Who needs the Cox-model anyway? Multiple time scales Competing risks 18/ 79

## Empirical rates for individuals

- ▶ At the *individual* level we introduce the **empirical rate**:  $(d, y)$ , — number of events  $(d \in \{0, 1\})$  during  $y$  risk time.
- ▶ A person contributes several observations of  $(d, y)$ , with associated covariate values.
- ▶ Empirical rates are **responses** in survival analysis.

Rates and Survival (surv-rate)

Survival Multiple timescales Competing risks Bendix Carstensen Rates and Survival Life-table estimators Kaplan-Meier estimators The Cox-model Who needs the Cox-model anyway? Multiple time scales Competing risks 14/ 79

## Poisson likelihood

The log-likelihood contributions from follow-up of **one** individual:

$$d_i \log(\lambda(t)) - \lambda(t)y_t, \quad t = t_1, \dots, t_n$$

is also the log-likelihood from several independent Poisson observations with mean  $\lambda(t)y_t$ , i.e.  $\log$ -mean  $\log(\lambda(t)) + \log(y)$   
Analysis of the rates,  $(\lambda)$  can be based on a Poisson model with log-link applied to empirical rates where:

- ▶  $\log(\lambda)$  is modelled by covariates
- ▶  $d$  is the response variable and
- ▶  $\log(y)$  is the offset variable, using the **poisson** family

Rates and Survival (surv-rate)

Survival Multiple timescales Competing risks Bendix Carstensen Rates and Survival Life-table estimators Kaplan-Meier estimators The Cox-model Who needs the Cox-model anyway? Multiple time scales Competing risks 19/ 79

## Poisson likelihood

The log-likelihood contributions from follow-up of **one** individual:

$$d_t \log(\lambda(t)) - \lambda(t) y_t, \quad t = t_1, \dots, t_n$$

is also the log-likelihood from several independent Poisson observations with mean  $\lambda(t) y_t$ , i.e.  $\log$ -mean  $\log(\lambda(t)) + \log(y_t)$

Analysis of the rates,  $(\lambda)$  can be based on a Poisson model with log-link applied to empirical rates  $(d, y)$

- ▶  $\log(\lambda)$  is modelled by covariates
- ▶  $(d, y)$  is the response variable
- ▶ ... using the `poisreg` family

## Survival analysis

- ▶ Response variable: Time to event,  $T$
- ▶ Censoring time,  $Z$
- ▶ We observe  $(\min(T, Z), \delta = 1\{T < Z\})$ .
- ▶ This gives time a special status, and mixes the response variable (risk)time with the covariate time(scale).
- ▶ Originates from clinical trials where everyone enters at time 0, and therefore  $Y = T - 0 = T$

## The life table method

The simplest analysis is by the "life-table method":

interval	alive	dead	cens.	
$i$	$n_i$	$d_i$	$l_i$	$p_i$
1	77	5	2	$5/(77 - 2/2) = 0.066$
2	70	7	4	$7/(70 - 4/2) = 0.103$
3	59	8	1	$8/(59 - 1/2) = 0.137$

$$p_i = P\{\text{death in interval } i\} = d_i / (n_i - l_i/2)$$

$$S(t) = (1 - p_1) \times \dots \times (1 - p_t)$$

25 / 79

## Observations for the lifetable

Life table is based on person-years and deaths accumulated in a short period.

Age-specific rates — cross-sectional!

Survival function:

$$S(t) = e^{-\int_0^t \lambda(a) da} = e^{-\sum_0^t \lambda(a)}$$

— assumes stability of rates to be interpretable for actual persons.

## Life table approach

- ▶ The **population** experience:
  - $D$ : Deaths (events).
  - $Y$ : Person-years (risk time).
- ▶ The classical lifetable analysis compiles these for prespecified intervals of age, and computes age-specific mortality **rates**.
- ▶ Data are collected crosssectionally, but interpreted longitudinally.
- ▶ The **rates** are the basic building blocks — used for construction of:
  - ▶ RRs
  - ▶ cumulative measures (survival and risk)

## The Kaplan-Meier Method

- ▶ The most common method of estimating the survival function.
- ▶ A non-parametric method.
- ▶ Divides time into small intervals where the intervals are defined by the unique times of failure (death).
- ▶ Based on conditional probabilities as we are interested in the probability a subject surviving the next time interval given that they have survived so far.

Kaplan-Meier estimators (km-na)

Multiple time scales  
Competing risks  
30 / 79

## The proportional hazards model

$$\lambda(t, x) = \lambda_0(t) \times \exp(x'\beta)$$

- ▶ The baseline hazard rate,  $\lambda_0(t)$ , is the hazard rate when all the covariates are 0 — since then  $\exp(x'\beta) = 1$
- ▶ The form of the above equation means that covariates act **multiplicatively** on the baseline hazard rate

## The proportional hazards model

$$\lambda(t, x) = \lambda_0(t) \times \exp(x'\beta)$$

- ▶ Time ( $t$ ) is a covariate (albeit modeled in a special way).
- ▶ The baseline hazard is a function of time and thus varies with time.
- ▶ No assumption about the shape of the underlying hazard function.
- ▶ — but you will never see the shape of the baseline hazard ...

## Interpreting Regression Coefficients

- ▶ If  $x_j$  is binary,  $\exp(\beta_j)$  is the estimated hazard ratio for subjects corresponding to  $x_j = 1$  compared to those where  $x_j = 0$ .
- ▶ If  $x_j$  is continuous,  $\exp(\beta_j)$  is the estimated increase/decrease in the hazard rate for a unit change in  $x_j$ .
- ▶ With more than one covariate, interpretation is similar, i.e.  $\exp(\beta_j)$  is the hazard ratio between persons who **only** differ with respect to covariate  $x_j$
- ▶ ... assuming that the effect of  $x_j$  is the same across all other covariate values

## Fitting a Cox-model in R

```
c0 <- coxph(Surv(stop,event) ~ number + size, data=bladder)
c0

Call:
coxph(formula = Surv(stop, event) ~ number + size, data = bladder)

      coef exp(coef) se(coef)      z      p
number 0.20491  1.22742  0.07036  2.912 0.00359
size    0.06135  1.06327  0.10328  0.594 0.55254

Likelihood ratio test=7.04 on 2 df, p=0.02963
n= 85, number of events= 47
```

What is the meaning of the two regression parameters?

## Plotting the base survival in R

```
plot(survfit(c0))
lines(survfit(c0), conf.int=F, lwd=3)
```

The `plot.coxph` plots the survival curve for a person with an average covariate value

- which is **not** the average survival for the population considered...
- and not necessarily meaningful

```
c( mean(bladder$number), mean(bladder$size) )
[1] 2.105882 2.011765
```

## A look at the Cox model

$$\lambda(t, x) = \lambda_0(t) \times \exp(x'\beta)$$

A model for the rate as a function of  $t$  and  $x$ .

The covariate  $t$  has a special status:

- Computationally, because all individuals contribute to (some of) the range of  $t$ .
- ... the scale along which time is split (the risk sets)
- Conceptually  $t$  is just a covariate that varies within individual.

## The Cox-likelihood as profile likelihood

- One parameter per death time to describe the effect of time (i.e. the chosen timescale).

$$\log(\lambda(t, x_i)) = \log(\lambda_0(t)) + \beta_1 x_{i1} + \dots + \beta_p x_{ip} = \alpha_t + \eta_i$$

- Profile likelihood:
  - Derive estimates of  $\alpha_t$  as function of data and  $\beta$ s — assuming constant rate between death times
  - Insert in likelihood, now only a function of data and  $\beta$ s
  - Turns out to be Cox's partial likelihood
  - The full likelihood is that of a Poisson model

## Plotting the base survival in R

You can plot the survival curve for specific values of the covariates, using the `newdata=` argument:

```
plot(survfit(c0))
lines(survfit(c0), conf.int=F, lwd=3)
lines(survfit(c0, newdata=data.frame(number=1, size=1)),
      lwd=2, col="limegreen")
text(par("usr")[2]+0.98, 1.00, "number=1, size=1",
     col="limegreen", font=2, adj=1)
```

Competing risks

41 / 79

## Implications

- The Cox-model is a special case of a Poisson model
- ... a model with one parameter per time (censoring or death) — typically hundreds of parameters
- A more sensible model would be one with a smooth effect of time.
- [bendixcarstensen.com/WntCma.pdf](http://bendixcarstensen.com/WntCma.pdf) gives a complete account
- ... but here is a quick tour of how-to

```
library(Epi)
library(popEpi)
library(mgcv)
library(survival)
data(lung)
lung <- transform( lung, sex=factor(sex,labels=c("M","F")),
                  time=time+runif(nrow(lung)) )
```

Set up a Lexis object (outcome as a factor), and split time in small intervals (at all times):

```
Lx <- Lexis( exit=list(tfe=time),
            exit.status=factor(status,labels=c("Alive","Dead")),
            data=lung )
```

NOTE: entry.status has been set to "Alive" for all.  
NOTE: entry is assumed to be 0 on the tfe timescale.

## Timescales

Mortality rates as a function of

- ▶ current age,  $a$
- ▶ duration of diabetes,  $d$
- ▶ age at diagnosis,  $e = a - d$  (not a timescale!)
- ▶  $\Rightarrow a - d - e = 0$   
— this relation must be kept in any dataset

Model for mortality depending on current age and age at entry:

$$\log(\mu(a, d)) = f(a) + h(e)$$

49 / 79

## Two variables: age and age at diagnosis

$$\log(\mu(a, d)) = f(a) + h(e)$$

**NOTE:** only superficially that this does not include duration since  $d = a - e$ , we may write:

$$\begin{aligned} \log(\mu(a, d)) &= f(a) + h(e) + \beta d - \beta d \\ &= f(a) + h(e) + \beta(a - e) - \beta d \\ &= (f(a) + \beta a) + (h(e) - \beta e) - \beta d \end{aligned}$$

We can claim any duration effect we like!

Prediction data frame for rates and survival — at what times do you want the rates and the survival shown for a 65 year old man, using the Poisson model with smooth effects:

```
ps <- gam.Lexis( sL, formula= ~ s(tfe) + sex + age )
```

mgcv::gam Poisson analysis of Lexis object sL with log link:  
Rates for the transition: Alive->Dead

```
nd <- data.frame( tfe=seq(0,900,20)+10, sex="M", age=65 )
rate <- ci.pred( ps, nd ) * 365.25 # per year, not per day
surv <- ci.surv( ps, nd, int=20 ) # int is interval between times in nd
```

Plot the rates and the survival function for 65 year old man

```
par( mfrow=c(1,2), mar=c(3,3,1,1), mgp=c(3,1,0)/1.6 )
matshade( nd$tfe, rate, lwd=2, log="y", plot=TRUE )
matshade( nd$tfe-10, surv, lwd=2, yaxs="i", ylim=c(0,1), plot=TRUE )
lines( survfit( cx, newdata=nd[1,] ), col='red' )
```

Who needs the Cox-model anyway? (WatOsa)

Survival  
Multiple timescales

Lifetable estimators  
Kaplan-Meier estimators  
The Cox-model  
Who needs the Cox-model anyway?  
Multiple time scales  
Competing risks  
50 / 79

## All three variables

Remember:  $a - d - e = 0$

$$\begin{aligned} \log(\mu(a, d)) &= f(a) + g(d) + h(e) \\ &= f(a) + g(d) + h(e) + \gamma(a - d - e) \\ &= (f(a) + \gamma a) + (g(d) - \gamma d) + (h(e) - \gamma e) \\ &= \tilde{f}(a) + \tilde{g}(d) + \tilde{h}(e) \end{aligned}$$

It makes no sense to show (any) one of the effects:

We can choose any slope for one of the effects, as long as we adjust the slopes of the two others.

## Getting it wrong

- ▶ It is commonly seen that a traditional survival analyses are conducted where transition to **Drug** is taken as event and deaths just counted as censorings.
- ▶ This is wrong; it will overestimate the probability of going on drugs.
- ▶ But nothing wrong with the estimate of the **rate** of initiating drugs.
- ▶ Only the calculation of the cumulative **probability** is wrong — the probability of having initiated a drug depends on both the rate of drug initiation **and** the mortality rate.

## Where is the error

- ▶ Error **only** in the calculations of the cumulative risk — the probability of transition to **Drug**.
- ▶ The “wrong” red line in the figure comes from omitting the green term  $\mu(s)$  (the mortality rate) from the formula
- ▶ The temptations:
  - ▶ the mathematics becomes nicer if you compute the wrong thing
  - ▶ it is what comes out of standard programs when regarding **Drug** as the only type of event. . .
  - ▶ the hazard **ratios** are correct.
  - ▶ . . . the program does not know there is a competing event if you don't tell
  - ▶ so the cumulative risks are wrong

## What are the wrong probabilities?

Probability of **Drug** under the **assumptions**:

- ▶ **Dead** does not occur
- ▶ **Drug** occurs at the same rate as when **Dead** was a possibility
- ▶ hypothetical scenario about which there is no information in data
- ▶ . . . and about which no data can be collected

## Competing risks — practicalities

- ▶ Cause-specific **rates** can be modeled separately: cause-specific rates and HRs are perfectly valid
- ▶ Regression models for cause-specific rates translates to predicted probabilities for given covariates
- ▶ Fine-Gray models
  - ▶ the subdistribution hazard for cause  $c$ :  $\frac{\partial}{\partial t} \log(1 - F_c(t))$
  - ▶ not a hazard, it's a mathematical transformation of the cumulative risk.
  - ▶ will not give probabilities that sum to 1 across causes
- . . . not recommended

## Getting the maths right

- ▶ rate of drug initiation (Alive→Drug):  $\lambda(t)$
- ▶ mortality before drug initiation (Alive→Dead):  $\mu(t)$
- ▶  $\Rightarrow$  probability of being alive without drug treatment at time  $t$  is:

$$S(t) = \exp\left(-\int_0^t \lambda(s) + \mu(s) ds\right)$$

- ▶ cumulative risk of **Drug** before time  $t$  is:

$$R_{\text{Drug}}(t) = \int_0^t \lambda(u) S(u) du = \int_0^t \lambda(u) \exp\left(-\int_0^u \lambda(s) + \mu(s) ds\right) du$$

— and similarly for cumulative risk of **Dead**

Competing risks (comp-risk)

## Competing risks summary

- ▶ No such thing as a competing risks analysis of event **rates**
- ▶ the competing risks aspect comes about only when you want to address **cumulative risk** of a particular event —in which case you probably want to look at cumulative risks of **all** types of events.
