## Rates and Survival

Multistate models:  
Occurrence rates, cumulative risks, competing risks,  
state probabilities with multiple states and time scales with R and Epi::Lexis  
Baker HDI, 22-23 February 2023

<http://bendixcarstensen.com/AdvCoh/courses/Melb-2023>

surv-rate

Timescale changed to  
"Time since diagnosis".

Survival and rate data (surv-rate)

6 / 130

# Survival data

Persons enter the study at some date.

Persons exit at a later date, either dead or alive.

Observation:

Actual time span to death ("event")

or

Some time alive ("at least this long")

Survival and rate data (surv-rate)

2 / 130

Patients ordered by survival time.

Survival and rate data (surv-rate)

7 / 130

# Examples of time-to-event measurements

- ▶ Time from diagnosis of cancer to death.
- ▶ Time from randomisation to death in a cancer clinical trial
- ▶ Time from HIV infection to AIDS.
- ▶ Time from marriage to 1st child birth.
- ▶ Time from marriage to divorce.
- ▶ Time to re-offending after being released from jail

Survival and rate data (surv-rate)

3 / 130

Survival times grouped into bands of survival.

Survival and rate data (surv-rate)

8 / 130

Each line a person

Each blob a death

Study ended at 31 Dec. 2003

Survival and rate data (surv-rate)

4 / 130

Patients ordered by survival status within each band.

Survival and rate data (surv-rate)

9 / 130

## Survival after Cervix cancer

Year	Stage I			Stage II		
	N	D	L	N	D	L
1	110	5	5	234	24	3
2	100	7	7	207	27	11
3	86	7	7	169	31	9
4	72	3	8	129	17	7
5	61	0	7	105	7	13
6	54	2	10	85	6	6
7	42	3	6	73	5	6
8	33	0	5	62	3	10
9	28	0	4	49	2	13
10	24	1	8	34	4	6

Life-table estimator of death probability:  $D/(N - L/2)$

Estimated risk of death in year 1 for Stage I women is  $5/107.5 = 0.0465$

Estimated 1 year survival is  $1 - 0.0465 = 0.9535$

## Survival after Cervix cancer

Year	Stage I			Stage II		
	N	D	L	N	D	L
1	110	5	5	234	24	3
2	100	7	7	207	27	11
3	86	7	7	169	31	9

Estimated risk in year 1 for Stage I women is  $5/107.5 = 0.0465$

Estimated risk in year 2 for Stage I women is  $7/96.5 = 0.0725$

Estimated risk in year 3 for Stage I women is  $7/82.5 = 0.0848$

Estimated 1 year survival is  $1 - 0.0465 = 0.9535$

Estimated 2 year survival is  $0.9535 \times (1 - 0.0725) = 0.8843$

Estimated 3 year survival is  $0.8843 \times (1 - 0.0848) = 0.8093$

This is the **life-table estimator** of the survival curve.

- ▶ no need to use 1 year intervals: 1 day intervals could be used
- ▶ very small intervals will leave at most 1 censoring or 1 death in each
- ▶ interval with 1 death and  $n_t$  persons at risk:  
 $P\{\text{Death}\} = 1/n_t$
- ▶ corresponding survival probability  $1 - 1/n_t = (n_t - 1)/n_t$
- ▶ interval with 0 deaths has survival probability 1
- ▶ multiply these over times with event to get survival function:

$$S(t) = \prod_{t \text{ with event}} (n_t - 1)/n_t$$

... you have the **Kaplan-Meier estimator**

## A multistate model: data

- ▶ Not really a model
- ▶ Data (observations)
  - ▶ sequence of transitions: (**when**, from state, to state)
  - ▶ sequence of: (current state, **time**, next state)
- ▶ Time: covariate or response? ... both, actually:
  - ▶ **when** something happens  
— is a **covariate** for rates:  
how large are rates at a given age, say
  - ▶ risk **time**: how long has the person been at risk  
— this is the part of the outcome
  - ▶ risk **time** is the difference between two **whens**
  - ▶ **whens** are usually dates

## A multistate model

- ▶ Target parameters:
  - ▶ Rates (the arrows)
  - ▶ State probabilities (being in a state at a given time)
  - ▶ Survival probability (being alive)
  - ▶ Sojourn times (how long time do you spend in a state)
  - ▶ Expected life time
  - ▶ Probability of ever visiting a state

## Data and parameter realms

- ▶ Data: events / (person)time  
— the rate dimension ( $\text{time}^{-1}$ )
- ▶ Target parameter dimensions:
  - ▶ rates ( $\text{dimension } \text{time}^{-1}$ )
  - ▶ probabilities:  
integrals of rates w.r.t. time, requires starting point  
—  $\text{dimension } \text{time}^{-1} \times \text{time} = \text{<none>}$
  - ▶ sojourn times:  
integrals of probabilities w.r.t. time.  
—  $\text{dimension } \text{<none>} \times \text{time} = \text{time}$

# Multistate models

## introduction

Multistate models:

Occurrence rates, cumulative risks, competing risks,

state probabilities with multiple states and time scales with R and Epi::Lexis

Baker HDI, 22-23 February 2023

<http://bendixcarstensen.com/AdvCoh/courses/Melb-2023>

## What is a statistical model

- ▶ Specification of a statistical machinery that could have generated data
- ▶ ... so with a statistical model we can simulate a data set
- ▶ The basis for the likelihood of data is the statistical **model**  
⇒ Estimation of parameters in the model
- ▶ Parameter estimates needed for prediction of rates (hazards)
- ▶ So we need the likelihood of  
the observed data  
given the model  
— a function of (the parameters of) the rates.

## A multistate model

## Data assumptions

- ▶ Individual, accurate data:
- ▶ Exact time of transition between states for all persons

# Lung cancer survival

## computations

Multistate models:

Occurrence rates, cumulative risks, competing risks,  
state probabilities with multiple states and time scales with R and Epi::Lexis  
Baker HDI, 22-23 February 2023

<http://bendixcarstensen.com/AdvCoh/courses/Melb-2023>

surv

We see that men have worse survival than women, but they are also a bit older (age is age at diagnosis of lung cancer):

```
> with(lung, tapply(age, sex, mean))
```

```
      M      W  
63.34058 61.07778
```

Formally there is a significant difference in survival between men and women

```
> survdiff(Surv(time, status==2) ~ sex, data = lung)
```

```
Call:  
survdiff(formula = Surv(time, status == 2) ~ sex, data = lung)
```

```
      N Observed Expected (O-E)^2/E (O-E)^2/V  
sex=M 138 112 91.6 4.55 10.3  
sex=W 90 53 73.4 5.68 10.3
```

```
Chisq= 10.3 on 1 degrees of freedom, p= 0.001
```

Lung cancer survival (surv)

23 / 130

## Prerequisites

```
> library(Epi)  
> library(popEpi)  
> # popEpi::splitMulti returns a data.frame rather than a data.table  
> options("popEpi.datatable" = FALSE)
```

Lung cancer survival (surv)

19 / 130

## Rates and rate-ratios

### ► Occurrence rate:

$$\lambda(t) = \lim_{h \rightarrow 0} P \{ \text{event in } (t, t+h] \mid \text{alive at } t \} / h$$

—measured in probability per time: time<sup>-1</sup>

- observation in a survival study: (exit status, time alive)
- empirical rate  $(d, y) = (\text{deaths}, \text{time})$
- the Cox model is a model for rates as function of time  $(t)$  and covariates  $(x_1, x_2)$ :

$$\lambda(t, x) = \lambda_0(t) \exp(\beta_1 x_1 + \beta_2 x_2)$$

—mortality depends on the person's sex and age, say.

- Data looks like data for a K-M analysis **plus** covariate values

Lung cancer survival (surv)

24 / 130

## The lung data set

```
> library(survival)  
> data(lung)  
> lung$sex <- factor(lung$sex,  
+                   levels = 1:2,  
+                   labels = c("M", "W"))  
> lung$time <- lung$time / (365.25/12)  
> head(lung)
```

inst	time	status	age	sex	ph.ecog	ph.karno	pat.karno	meal	cal	wt.loss
1	3	10.053388	2	74	M	1	90	100	1175	NA
2	3	14.948665	2	68	M	0	90	90	1225	15
3	3	33.182752	1	56	M	0	90	90	NA	15
4	5	6.899384	2	57	M	1	90	60	1150	11
5	1	29.010267	2	60	M	0	100	90	NA	0
6	12	33.577002	1	74	M	1	50	80	513	0

Lung cancer survival (surv)

20 / 130

## Rates and rate-ratios: Simple Cox model

Now explore how sex and age (at diagnosis) influence the mortality—note that in a Cox-model we are addressing the mortality rate and not the survival:

```
> c0 <- coxph(Surv(time, status == 2) ~ sex, data = lung)  
> c1 <- coxph(Surv(time, status == 2) ~ sex + age, data = lung)  
> summary(c1)  
> ci.exp(c0)  
> ci.exp(c1)
```

What variables from `lung` are we using?

Lung cancer survival (surv)

25 / 130

## Survival function

- Use `survfit` to construct the Kaplan-Meier estimator of overall survival:

```
> ?Surv  
> ?survfit  
> km <- survfit(Surv(time, status == 2) ~ 1, data = lung)  
> km  
Call: survfit(formula = Surv(time, status == 2) ~ 1, data = lung)
```

```
      n events median 0.95LCL 0.95UCL  
[1,] 228 165 10.2 9.36 11.9  
> # summary(km) # very long output
```

Lung cancer survival (surv)

21 / 130

```
> c0 <- coxph(Surv(time, status == 2) ~ sex, data = lung)  
> c1 <- coxph(Surv(time, status == 2) ~ sex + age, data = lung)  
> summary(c1)
```

```
Call:  
coxph(formula = Surv(time, status == 2) ~ sex + age, data = lung)
```

```
n= 228, number of events= 165
```

```
      coef exp(coef) se(coef) z Pr(>|z|)  
sexW -0.513219 0.598566 0.167458 -3.065 0.00218 **  
age 0.017045 1.017191 0.009223 1.848 0.06459 .
```

```
---  
Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
```

```
      exp(coef) exp(-coef) lower .95 upper .95  
sexW 0.5986 1.6707 0.4311 0.8311  
age 1.0172 0.9831 0.9990 1.0357
```

```
Concordance= 0.603 (se = 0.025 )  
Likelihood ratio test= 14.12 on 2 df, p=9e-04  
Wald test = 13.47 on 2 df, p=0.001  
Score (logrank) test = 13.72 on 2 df, p=0.001
```

Lung cancer survival (surv)

26 / 130

We can plot the survival curve—this is the default plot for a `survfit` object:

```
> plot(km)
```

What is the median survival? What does it mean? Explore if survival patterns between men and women are different:

```
> kms <- survfit(Surv(time, status == 2) ~ sex, data = lung)  
> kms  
Call: survfit(formula = Surv(time, status == 2) ~ sex, data = lung)
```

```
      n events median 0.95LCL 0.95UCL  
sex=M 138 112 8.87 6.97 10.2  
sex=W 90 53 14.00 11.43 18.1
```

Lung cancer survival (surv)

22 / 130

```
> ci.exp(c0)  
      exp(Est.) 2.5% 97.5%  
sexW 0.5880028 0.4237178 0.8159848  
> ci.exp(c1)  
      exp(Est.) 2.5% 97.5%  
sexW 0.598566 0.4310936 0.8310985  
age 1.017191 0.9989686 1.0357467
```

What do these estimates mean?

$$\lambda(t, x) = \lambda_0(t) \exp(\beta_1 x_1 + \beta_2 x_2)$$

Where is  $\beta_1$ ? Where is  $\beta_2$ ? Where is  $\lambda_0(t)$ ?

What is the mortality RR for a 10 year age difference?

Lung cancer survival (surv)

27 / 130

If mortality is assumed constant ( $\lambda(t) = \lambda$ ), then the likelihood for the Cox-model is equivalent to a Poisson likelihood, which can be fitted using the `poisreg` family from the `Epi` package:

```
> ?poisreg

> p1 <- glm(cbind(status == 2, time) ~ sex + age,
+         family = poisreg,
+         data = lung)
> ci.exp(p1) # Poisson
      exp(Est.)      2.5%      97.5%
(Intercept) 0.03255152 0.01029228 0.1029511
sexW       0.61820515 0.44555636 0.8577537
age        1.01574132 0.99777446 1.0340317

> ci.exp(c1) # Cox
      exp(Est.)      2.5%      97.5%
sexW  0.598566 0.4310936 0.8310985
age   1.017191 0.9989686 1.0357467
```

## Dividing follow-up time

- ▶ Survival for a time span:  $y = t_x - t_e$
- ▶ Subdivided in  $N$  intervals, each of length  $h = y/N$
- ▶ Survival probability for the entire span from  $t_e$  to  $t_x$  is the **product** of probabilities of surviving each of the small intervals, conditional on being alive at the beginning each interval:

$$P \{\text{survive } t_e \text{ to } t_x\} \approx (1 - \lambda h)^N = \left(1 - \frac{\lambda y}{N}\right)^N$$

Sex and age effects are quite close between the Poisson and the Cox models.

Poisson model has an intercept term, the estimate of the (assumed) constant underlying mortality.

The risk time part of the response (second argument in the `cbind`) was entered in units of months (remember we rescaled in the beginning?), the `(Intercept)` (taken from the `ci.exp`) is a rate per 1 person-month.

What age and sex does the `(Intercept)` refer to?

```
> ci.exp(p1) # Poisson
      exp(Est.)      2.5%      97.5%
(Intercept) 0.03255152 0.01029228 0.1029511
sexW       0.61820515 0.44555636 0.8577537
age        1.01574132 0.99777446 1.0340317
```

## Dividing follow-up time

- ▶ From mathematics it is known that  $(1 + x/n)^n \rightarrow \exp(x)$  as  $n \rightarrow \infty$  (some define  $\exp(x)$  this way).
- ▶ So if we divide the time span  $y$  in small pieces we will have that  $N \rightarrow \infty$ :

$$P \{\text{survive } t_e \text{ to } t_x\} \approx \left(1 - \frac{\lambda y}{N}\right)^N \rightarrow \exp(-\lambda y), \quad N \rightarrow \infty \quad (2)$$

- ▶ The contribution to the likelihood from a person observed for a time span of length  $y$  is  $\exp(-\lambda y)$ , and the contribution to the log-likelihood is therefore  $-\lambda y$ .

## poisreg and poisson

```
poisreg: cbind(d,y) ~ ...

> p1 <- glm(cbind(status == 2, time) ~ sex + age,
+         family = poisreg,
+         data = lung)

poisson: d ~ ... + offset(log(y))

> px <- glm(status == 2 ~ sex + age + offset(log(time)),
+         family = poisson,
+         data = lung)
> ## or:
> px <- glm(status == 2 ~ sex + age,
+         offset = log(time),
+         family = poisson,
+         data = lung)
```

## Dividing follow-up time

- ▶ A person dying at the end of the last interval, the contribution to the likelihood from the last interval will be
- ▶ the probability surviving till just before the end of the interval,
- ▶ **multiplied** by
- ▶ the probability of dying in the last tiny instant (of length  $\epsilon$ ) of the interval
- ▶ The probability of dying in this tiny instant is  $\lambda \epsilon$
- ▶ log-likelihood contribution from this last instant is  $\log(\lambda \epsilon) = \log(\lambda) + \log(\epsilon)$ .

## Likelihood and records

Suppose a person is alive from  $t_e$  (entry) to  $t_x$  (exit) and that the person's status at  $t_x$  is  $d$ , where  $d = 0$  means alive and  $d = 1$  means dead. If we choose, say, two time points,  $t_1, t_2$  between  $t_e$  and  $t_x$ , standard use of conditional probability (formally, repeated use of Bayes' formula) gives

$$P \{d \text{ at } t_x \mid \text{entry at } t_e\} = P \{\text{survive } (t_e, t_1] \mid \text{alive at } t_e\} \times \\ P \{\text{survive } (t_1, t_2] \mid \text{alive at } t_1\} \times \\ P \{\text{survive } (t_2, t_x] \mid \text{alive at } t_2\} \times \\ P \{d \text{ at } t_x \mid \text{alive just before } t_x\}$$

## Total likelihood

The total likelihood for one person is the product of all these terms from the follow-up intervals ( $i$ ) for the person, and the log-likelihood ( $\ell$ ) is therefore the sum of the log-likelihood terms:

$$\ell(\lambda) = \sum_i (-\lambda y_i + d_i \log(\lambda) + d_i \log(\epsilon)) \\ = \sum_i (d_i \log(\lambda) - \lambda y_i) + \sum_i d_i \log(\epsilon)$$

The last term does not depend on  $\lambda$ , so it can be ignored

## Rates and likelihood

For a start assume that the mortality is constant over time  $\lambda(t) = \lambda$ :

$$P \{\text{death during } (t, t+h]\} \approx \lambda h \quad (1) \\ \Rightarrow P \{\text{survive } (t, t+h]\} \approx 1 - \lambda h$$

where the approximation gets better the smaller  $h$  is.

## Total log-likelihood

- ▶ ... for the follow up of 1 person is (the **rate** likelihood):

$$\sum_i (d_i \log(\lambda) - \lambda y_i)$$

- ▶ this is also the likelihood for independent Poisson variates  $d_i$  with means  $\lambda y_i$ .
- ▶ even though the  $d_i$ s are neither Poisson nor independent
- ▶ Different models can have the same (log)likelihood:
  - ▶ model for follow-up of a person  $(d_i, y_i)$ , constant rate  $\lambda$
  - ▶ model for independent Poisson variates  $(d_i)$ , mean  $\lambda y_i$

Probability

$$P(d \text{ at } t_x | \text{entry } t_e)$$

$$= P(\text{surv } t_e \rightarrow t_1 | \text{entry } t_e) \\ \times P(\text{surv } t_1 \rightarrow t_2 | \text{entry } t_1) \\ \times P(d \text{ at } t_x | \text{entry } t_2)$$

log-Likelihood

$$d \log(\lambda) - \lambda y$$

$$= 0 \log(\lambda) - \lambda y_1 \\ + 0 \log(\lambda) - \lambda y_2 \\ + d \log(\lambda) - \lambda y_3$$

## Representation of follow-up: Lexis object

```
> Ll <- Lexis(exit = list(tfl = time),
+           exit.status = factor(status,
+                               levels = 1:2,
+                               labels = c("Alive", "Dead")),
+           data = lung)
NOTE: entry.status has been set to "Alive" for all.
NOTE: entry is assumed to be 0 on the tfl timescale.
> head(Ll)
```

90											15
90											NA
90											15
60											11

## New variables in a Lexis object

**tfl**: time from lung cancer **at the time of entry**, therefore it is 0 for all persons; the entry time is 0 from the date of lung cancer. Defines a **timescale** with name **tfl**.

**lex.dur**: the **length** of time a person is in state **lex.Cst**, here measured in months, because **time** is.

**lex.Cst**: Current **state**, the state in which the **lex.dur** time is spent.

**lex.Xst**: eXit **state**, the state to which the person moves after the **lex.dur** time in **lex.Cst**.

**lex.id**: an id of each record in the source dataset. Can be explicitly set by **id=**.

Probability

$$P(\text{surv } t_e \rightarrow t_x | \text{entry } t_e)$$

$$= P(\text{surv } t_e \rightarrow t_1 | \text{entry } t_e) \\ \times P(\text{surv } t_1 \rightarrow t_2 | \text{entry } t_1) \\ \times P(\text{surv } t_2 \rightarrow t_x | \text{entry } t_2)$$

log-Likelihood

$$0 \log(\lambda) - \lambda y$$

$$= 0 \log(\lambda) - \lambda y_1 \\ + 0 \log(\lambda) - \lambda y_2 \\ + 0 \log(\lambda) - \lambda y_3$$

Probability

$$P(\text{event at } t_x | \text{entry } t_e)$$

$$= P(\text{surv } t_e \rightarrow t_1 | \text{entry } t_e) \\ \times P(\text{surv } t_1 \rightarrow t_2 | \text{entry } t_1) \\ \times P(\text{event at } t_x | \text{entry } t_2)$$

log-Likelihood

$$1 \log(\lambda) - \lambda y$$

$$= 0 \log(\lambda) - \lambda y_1 \\ + 0 \log(\lambda) - \lambda y_2 \\ + 1 \log(\lambda) - \lambda y_3$$

## Lexis object: Overview of follow-up

Overkill?

The point is that the machinery generalizes to multistate data.

```
> summary(Ll)
```

Transitions:

From	To	Alive	Dead	Records	Events	Risk time	Persons
Alive	Alive	63	165	228	165	2286.42	228

What is the average follow-up time for persons?

Probability

$$P(d \text{ at } t_x | \text{entry } t_e)$$

$$= P(\text{surv } t_e \rightarrow t_1 | \text{entry } t_e) \\ \times P(\text{surv } t_1 \rightarrow t_2 | \text{entry } t_1) \\ \times P(d \text{ at } t_x | \text{entry } t_2)$$

log-Likelihood

$$d \log(\lambda) - \lambda y$$

$$= 0 \log(\lambda) - \lambda y_1 \\ + 0 \log(\lambda) - \lambda y_2 \\ + d \log(\lambda) - \lambda y_3$$

```
> boxes(Ll, boxpos = TRUE, scale.Y = 12, digits.R = 2)
```

Explain the numbers in the graph.

Probability

$$P(d \text{ at } t_x | \text{entry } t_e)$$

$$= P(\text{surv } t_e \rightarrow t_1 | \text{entry } t_e) \\ \times P(\text{surv } t_1 \rightarrow t_2 | \text{entry } t_1) \\ \times P(d \text{ at } t_x | \text{entry } t_2)$$

log-Likelihood

$$d \log(\lambda) - \lambda y$$

$$= 0 \log(\lambda_1) - \lambda_1 y_1 \\ + 0 \log(\lambda_2) - \lambda_2 y_2 \\ + d \log(\lambda_3) - \lambda_3 y_3$$

— allows different rates ( $\lambda_i$ ) in each interval

Cox model using the Lexis-specific variables:

```
> cl <- coxph(Surv(tfl,
+             tfl + lex.dur,
+             lex.Xst == "Dead") ~ sex + age,
+            data = Ll)
```

Surv(from-time, to-time, event indicator)

Using the Lexis features:

```
> cL <- coxph.Lexis(Ll, tfl ~ sex + age)
survival::coxph analysis of Lexis object Ll:
Rates for the transition:
```

Alive->Dead

Baseline timescale: tfl

```
> round(cbind(ci.exp(cL),
+             ci.exp(cL)), 3)
```

	exp(Est.)	2.5%	97.5%	exp(Est.)	2.5%	97.5%
sexW	0.599	0.431	0.831	0.599	0.431	0.831
age	1.017	0.999	1.036	1.017	0.999	1.036

The crude Poisson model:

```
> pc <- glm(cbind(lex.Xst == "Dead", lex.dur) ~ sex + age,
+         family = poisreg,
+         data = L1)
```

or even simpler, by using the Lexis features:

```
> pL <- glm.Lexis(L1, ~ sex + age)
stats::glm Poisson analysis of Lexis object L1 with log link:
Rates for the transition:
Alive->Dead
> round(cbind(ci.exp(pL),
+         ci.exp(pc)), 3)
              exp(Est.) 2.5% 97.5% exp(Est.) 2.5% 97.5%
(Intercept) 0.033 0.010 0.103 0.033 0.010 0.103
sexW        0.618 0.446 0.858 0.618 0.446 0.858
age         1.017 0.999 1.036 1.017 0.998 1.034
```

Comparing with estimates from the Cox-model and from the model with constant baseline:

```
> round(cbind(ci.exp(c1),
+         ci.exp(ps, subset = c("sex", "age")),
+         ci.exp(pc, subset = c("sex", "age"))), 3)
              exp(Est.) 2.5% 97.5% exp(Est.) 2.5% 97.5% exp(Est.) 2.5% 97.5%
sexW        0.599 0.431 0.831 0.599 0.431 0.831 0.618 0.446 0.858
age         1.017 0.999 1.036 1.017 0.998 1.035 1.016 0.998 1.034
```

## Poisson and Cox model

The crude Poisson model is a Cox-model with the (quite brutal) assumption that baseline rate is constant over time.

But results are similar:

```
> round(cbind(ci.exp(cL),
+         ci.exp(pL)[-1,]), 3)
              exp(Est.) 2.5% 97.5% exp(Est.) 2.5% 97.5%
sexW        0.599 0.431 0.831 0.618 0.446 0.858
age         1.017 0.999 1.036 1.016 0.998 1.034
```

## But where is the baseline hazard?

ps is a model for the hazard so we can predict the value of it at defined values for the covariates in the model:

```
> prf <- data.frame(tfl = seq(0, 30, 0.2),
+         sex = "W",
+         age = 60)
```

We can over-plot with the predicted rates from the model where mortality rates are constant, the only change is the model (pc instead of ps):

```
> matshade(prf$tfl, ci.pred(ps, prf),
+         plot = TRUE, log = "y", lwd = 3)
> matshade(prf$tfl, ci.pred(pc, prf), lty = 3, lwd = 3)
```

## Baseline hazard: splitting time

```
> S1 <- splitMulti(L1, tfl = 0:36)
> summary(L1)
Transitions:
To
From Alive Dead Records: Events: Risk time: Persons:
Alive 63 165 228 165 2286.42 228
> summary(S1)
Transitions:
To
From Alive Dead Records: Events: Risk time: Persons:
Alive 2234 165 2399 165 2286.42 228
```

What happened to no. records?

What happened to amount of risk time?

What happened to no. events?

## Here is the baseline hazard!

What are the units on the y-axis? Describe the mortality rates

```
> wh <- names(L1)[1:10] # names of variables in some order
> subset(L1, lex.id == 10)[,wh]
lex.id tfl lex.dur lex.Cst lex.Xst inst time status age sex
10 0 5.45 Alive Dead 7 5.454 2 61 M
> subset(S1, lex.id == 10)[,wh]
lex.id tfl lex.dur lex.Cst lex.Xst inst time status age sex
10 0 1.00 Alive Alive 7 5.454 2 61 M
10 1 1.00 Alive Alive 7 5.454 2 61 M
10 2 1.00 Alive Alive 7 5.454 2 61 M
10 3 1.00 Alive Alive 7 5.454 2 61 M
10 4 1.00 Alive Alive 7 5.454 2 61 M
10 5 0.45 Alive Dead 7 5.454 2 61 M
```

In S1 each record now represents a small interval of follow-up for a person, so each person has many records.

## Survival function and hazard function

$$S(t) = \exp\left(-\int_0^t \lambda(u) du\right)$$

Simple, but the CI for  $S(t)$  not so simple...

Implemented in the ci.surv function

Arguments: 1:model, 2:prediction data frame, 3:equidistance

Prediction data frame must correspond to a sequence of equidistant time points:

```
> matshade(prf$tfl, ci.surv(ps, prf, intl = 0.2),
+         plot = TRUE, ylim = 0:1, lwd = 3)
> lines(prf$tfl, ci.surv(pc, prf, intl = 0.2)[,1], col="blue")
> lines(survfit(c1, newdata = data.frame(sex = "W", age = 60)),
+         lwd = 2, lty = 1, col="magenta")
```

## Natural splines for baseline hazard

```
> ps <- glm(cbind(lex.Xst == "Dead", lex.dur)
+         ~ Ns(tfl, knots = seq(0, 36, 12)) + sex + age,
+         family = poisreg,
+         data = S1)
or even simpler:
> ps <- glm.Lexis(S1, ~ Ns(tfl, knots = seq(0, 36, 12)) + sex + age)
stats::glm Poisson analysis of Lexis object S1 with log link:
Rates for the transition:
Alive->Dead
> ci.exp(ps)
              exp(Est.) 2.5% 97.5%
(Intercept) 0.0189837 0.005700814 0.06321569
Ns(tfl, knots = seq(0, 36, 12))1 2.4038681 0.809442081 7.13896863
Ns(tfl, knots = seq(0, 36, 12))2 4.1500822 0.436273089 39.47798357
Ns(tfl, knots = seq(0, 36, 12))3 0.8398973 0.043928614 16.05849662
sexW        0.5987171 0.431232662 0.83124998
age         1.0165872 0.998377104 1.03512945
```

## Survival functions

## Hazard and survival functions

## K-M estimator and smooth Poisson model

Kaplan-Meier estimator and compared to survival from corresponding Poisson-model, which is one with time (`tf1`) as the only covariate:

```
> par(mfrow=c(1,2))
> pk <- glm(cbind(lex.Xst == "Dead",
+               lex.dur) ~ Ns(tf1, knots = seq(0, 36, 12)),
+         family = poisreg,
+         data = S1)
> # hazard
> matshade(prf$tf1, ci.pred(pk, prf),
+         plot = TRUE, log = "y", lwd = 3, ylim = c(0.01,1))
> # survival from smooth model
> matshade(prf$tf1, ci.surv(pk, prf, intl = 0.2) ,
+         plot = TRUE, lwd = 3, ylim = 0:1)
> # K-M estimator
> lines(km, lwd = 2)
```

## K-M estimator and smooth Poisson model

We can explore how the tightness of the knots in the smooth model influence the underlying hazard and the resulting survival function:

```
> zz <- function(dk) # distance between knots
+ {
+   par(mfrow=c(1,2))
+   kn <- seq(0, 36, dk)
+   pk <- glm(cbind(lex.Xst == "Dead",
+                 lex.dur) ~ Ns(tf1, knots = kn),
+           family = poisreg,
+           data = S1)
+   matshade(prf$tf1, ci.pred(pk, prf),
+           plot = TRUE, log = "y", lwd = 3, ylim = c(0.01,1))
+   rug(kn, lwd=3)
+   matshade(prf$tf1, ci.surv(pk, prf, intl = 0.2) ,
+           plot = TRUE, lwd = 3, ylim = 0:1)
+   lines(km, lwd = 2, col = "forestgreen")
+ }
> zz(12)
```

## Survival analysis summary

- ▶ 1 to 1 correspondence between
  - ▶ hazard function and starting point
  - ▶ survival function
- ▶ K-M and Cox use a very detailed baseline hazard (omits it)
- ▶ Smooth parametric hazard function more credible:
  - ▶ Define Lexis object
  - ▶ Split along time
  - ▶ Fit Poisson model
  - ▶ Prediction data frame
  - ▶ ci.pred to get baseline rates
  - ▶ ci.surv to get baseline survival

## Cut follow-up at the date of Ins

```
> Ldm <- sortLexis(Ldm)

```

## Survival function?

- ▶ Regarding either Dead or Ins as censorings — or neither?
- ▶ **Simple survival:** what is the probability of being in each of the states Alive and Dead
  - depends on **one** rate, Alive → Dead
- ▶ **Competing risks:** the probability of being in each of the states DM, Ins and Dead
  - depends on **two** rates, DM → Ins and DM → Dead

## Survival and cumulative risk functions

## Survival function and Cumulative risk function

survfit does the trick; the requirements are:

1. (start, stop, event) arguments to **Surv**
2. the third argument to the **Surv** function is a factor
3. an **id** argument is given, pointing to an id variable that links together records belonging to the same person.
4. the initial state (DM) must be the first level of the factor **lex.Xst**

## Survival and cumulative risk functions

## Survival function and Cumulative risk function

```
> levels(Adm$lex.Xst)
[1] "DM" "Ins" "Dead"
> m3 <- survfit(Surv(tfd, tfd + lex.dur, lex.Xst) ~ 1,
+             id = lex.id,
+             data = Adm)
> # names(m3)
> m3$pstates
[1] "(s0)" "Ins" "Dead"
> head(cbind(time = m3$time, m3$pstate))
      time

```

—this is called the Aalen-Johansen estimator of state probabilities

## Survival function and cumulative risks—don't

$$S(t) = \exp\left(-\int_0^t \lambda(u) + \mu(u) du\right)$$

$$R_{\text{Dead}}(t) = \int_0^t \mu(u) S(u) du$$

$$R_{\text{Ins}}(t) = \int_0^t \lambda(u) S(u) du$$

$$= \int_0^t \lambda(u) \exp\left(-\int_0^u \lambda(s) + \mu(s) ds\right) du$$

$$\neq \int_0^t \lambda(u) \exp\left(-\int_0^u \lambda(s) ds\right) du$$

$$= 1 - \exp\left(-\int_0^t \lambda(s) ds\right) \text{ — nice formula, but wrong!}$$

Probability of Ins assuming Dead does not exist and rate of Ins unchanged!

## Survival function and cumulative risks—formulae

$$S(t) = \exp\left(-\int_0^t \lambda(u) + \mu(u) du\right)$$

$$R_{\text{Dead}}(t) = \int_0^t \mu(u) S(u) du$$

$$R_{\text{Ins}}(t) = \int_0^t \lambda(u) S(u) du$$

$$= \int_0^t \lambda(u) \exp\left(-\int_0^u \lambda(s) + \mu(s) ds\right) du$$

$$S(t) + R_{\text{Ins}}(t) + R_{\text{Dead}}(t) = 1, \quad \forall t$$

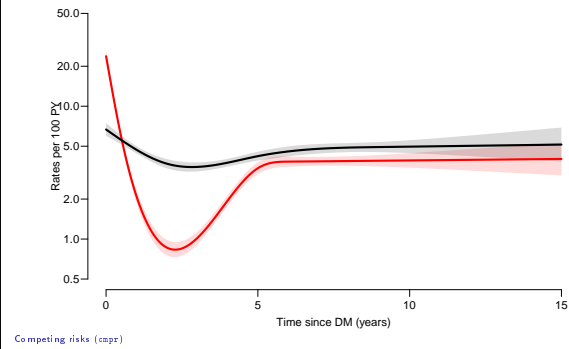

## Survival function and cumulative risks—don't

```
> m2 <- survfit(Surv(tfd,
+                 tfd + lex.dur,
+                 lex.Xst == "Ins") ~ 1,
+             data = Adm)
> M2 <- survfit(Surv(tfd,
+                 tfd + lex.dur,
+                 lex.Xst == "Dead") ~ 1,
+             data = Adm)
> par(mfrow = c(1,2))
> mat2pol(m3$pstate, c(2,3,1), x = m3$time,
+         col = c("red", "black", "transparent"),
+         xlim=c(0,15), xaxs="i",
+         yaxs = "i", xlab = "time since DM", ylab = "" )
> lines(m2$time, 1 - m2$surv, lwd = 3, col = "red" )
> mat2pol(m3$pstate, c(3,2,1), x = m3$time, yaxs = "i",
+         col = c("black", "red", "transparent"),
+         xlim=c(0,15), xaxs="i",
+         yaxs = "i", xlab = "time since DM", ylab = "" )
> lines(M2$time, 1 - M2$surv, lwd = 3, col = "black" )
```

## Survival and cumulative risk functions

## Survival and cumulative risk functions

## Cause-specific rates

- ▶ There is nothing wrong with modeling the cause-specific event-rates, the problem lies in how you transform them into probabilities.
- ▶ The relevant model for a competing risks situation normally consists of separate models for each of the cause-specific rates.
- ▶ These models have no common parameters (effects of time or other covariates are not constrained to be the same).
- ▶ ... not for technical or statistical reasons, but for **substantial** reasons:  
it is unlikely that rates of different types of event (Insulin initiation and death, say) depend on time in the same way.

## Survival and cumulative risk functions

## Cause-specific rates

```
> Sdm <- splitMulti(Adm, tfd = seq(0, 20, 0.1))

```

## Integrals with R

- ▶ Integrals look scary to many people, but they are really just areas under curves.
- ▶ In R, a curve of the function  $\mu(t)$  is a set of two vectors: one vector of  $t$ s and one vector  $y = \mu(t)$ s.
- ▶ When we have a model such as the `glm` above that estimates the mortality as a function of time (`tfd`), we can get the mortality as a function of time by first choosing the timepoints, say from 0 to 15 years in steps of 0.01 year ( $\approx 4$  days)
- ▶ Using `ci.pred` on this gives the predicted rates
- ▶ Then use the formulae with all the integrals to get the state probabilities.

## Cause-specific rates

```
> round(cbind(
+ with(subset(Sdm, lex.Xst == "Ins"), quantile(tfd + lex.dur, 0:4/4)),
+ with(subset(Sdm, lex.Xst == "Dead"), quantile(tfd + lex.dur, 0:4/4))), 2)
      [,1] [,2]
0%    0.01 0.01
25%   0.07 1.15
50%   1.07 3.01
75%   5.19 5.69
100% 13.74 14.38
> ikn <- c(0, 0.5, 3, 10)

```

## Integrals with R

```
> t <- seq(0, 15, 0.01)
> nd <- data.frame(tfd = t)
> mu <- ci.pred(Dead.glm, nd)[,1]
> head(cbind(t, mu))
      t      mu
1 0.00 0.061567
2 0.01 0.061372
3 0.02 0.061177
4 0.03 0.060983
5 0.04 0.060790
6 0.05 0.060597
> plot(t, mu, type="l", lwd = 3,
+ xlim = c(0, 7), xaxs = "i",
+ ylim = c(0, 0.1), yaxs = "i")
> polygon(t[c(1:501,501:i)], c(mu[1:501], rep(0, 501)),
+ col = "gray", border = "transparent")
> abline(v=0:50/10, col="white")
```

## Cause-specific rates

```
> int <- 0.01
> nd <- data.frame(tfd = seq(0, 15, int))
> l.glm <- ci.pred(Ins.glm, nd)
> m.glm <- ci.pred(Dead.glm, nd)
> matshade(nd$tfd,
+ cbind(l.glm, m.glm) * 100,
+ plot = TRUE,
+ yaxs="i", ylim = c(0, 20),
+ # log = "y", ylim = c(2, 20),
+ col = rep(c("red", "black"), 2), lwd = 3,
+ xlab = "Time since DM (years)",
+ ylab = "Rates per 100 PY")
```

## Integrals with R

## Numerical integration with R

```
> mid <- function(x) x[-1] - diff(x) / 2
> (x <- c(1:5, 7, 10))
[1] 1 2 3 4 5 7 10
> mid(x)
[1] 1.5 2.5 3.5 4.5 6.0 8.5
```

`mid(x)` is a vector that is 1 shorter than the vector `x`, just as `diff(x)` is.

So if we want the integral over the period 0 to 5 years, we want the sum over the first 500 intervals, corresponding to the first 501 interval endpoints:

```
> cbind(diff(t), mid(mu))[1:5,]
[,1] [,2]
2 0.01 0.061470
3 0.01 0.061275
4 0.01 0.061080
5 0.01 0.060887
6 0.01 0.060694
```

Competing risks (cpr)

97 / 130

## Cumulative risks from parametric models

So now plot the cumulative risks of being in each of the states (the `Crisk` component):

```
> matshade(as.numeric(dimnames(cR$Crisk)[[1]]),
+         cbind(cR$Crisk[,1,],
+             cR$Crisk[,2,],
+             cR$Crisk[,3,]), plot = TRUE,
+         lwd = 2, col = c("limegreen", "red", "black"))
```

Competing risks (cpr)

102 / 130

## Numerical integration with R

In practice we will want the integral function of  $\mu$ , so for every  $t$  we want  $M(t) = \int_0^t \mu(s) ds$ . This is easily accomplished by the function `cumsum`:

```
> Mu <- c(0, cumsum(diff(t) * mid(mu)))
> head(cbind(t, Mu))
  t      Mu
0 0.00 0.0000000
2 0.01 0.0006147
3 0.02 0.0012274
4 0.03 0.0018383
5 0.04 0.0024471
6 0.05 0.0030541
```

Note the first value which is the integral from 0 to 0, so by definition 0.

Competing risks (cpr)

98 / 130

## Survival and cumulative risk functions

Competing risks (cpr)

103 / 130

## Cumulative risks from parametric models

If we have estimates of  $\lambda$  and  $\mu$  as functions of time, we can derive the cumulative risks.

In practice this will be by numerical integration; compute the rates at closely spaced intervals and evaluate the integrals as sums. This is easy.

What is not so easy is to come up with confidence intervals for the cumulative risks.

Competing risks (cpr)

99 / 130

## Stacked probabilities: (matrix 2 polygons)

```
> mat2pol(cR$Crisk[,3:1,1], col = c("forestgreen", "red", "black")[3:1])
```

1st argument to `mat2pol` must be a 2-dimensional matrix, with rows representing the  $x$ -axis of the plot, and columns states.

The component `Srisk` has the confidence limits of the stacked probabilities:

```
> mat2pol(cR$Crisk[,3:1,1], col = c("forestgreen", "red", "black")[3:1])
> matlines(as.numeric(dimnames(cR$Srisk)[[1]]),
+         cbind(cR$Srisk[, "Dead", 2:3],
+             cR$Srisk[, "Dead+Ins", 2:3]),
+         lty = "32", lwd = 2, col = gray(0.7))
```

Competing risks (cpr)

104 / 130

## Simulation of cumulative risks: `ci.Crisk`

1. a random vector from the multivariate normal distribution with
  - ▶ mean equal to the parameters of the model,
  - ▶ variance-covariance equal to the estimated variance-covariance of the parameter estimates
2. use this to generate a simulated set of rates ( $\lambda(t)$ ,  $\mu(t)$ ), evaluated at closely spaced times
3. derive state probabilities at these times by numerical integration
4. repeat to obtain, say, 1000 sets of state probabilities at these times
5. derive confidence intervals for the state probabilities as the 2.5 and 97.5 percentiles of the state probabilities at each time

This machinery is implemented in the function `ci.Crisk` in `Epi`

Competing risks (cpr)

100 / 130

## Survival and cumulative risk functions

Competing risks (cpr)

105 / 130

## Cumulative risks from parametric models

```
> cR <- ci.Crisk(mods = list(Ins = Ins.glm,
+                          Dead = Dead.glm),
+               nd = nd)
NOTE: Times are assumed to be in the column tfd at equal distances of 0.01
> str(cR)
List of 4
 $ Crisk: num [1:1501, 1:3, 1:3] 1 0.996 0.993 0.989 0.986 ...
 .. attr(*, "dimnames")=List of 3
 .. ..$ tfd : chr [1:1501] "0" "0.01" "0.02" "0.03" ...
 .. ..$ cause: chr [1:3] "Surv" "Ins" "Dead"
 .. ..$ : chr [1:3] "50%" "2.5%" "97.5%"
 $ Srisk: num [1:1501, 1:2, 1:3] 0 0.000618 0.001232 0.001841 0.002447 ...
 .. attr(*, "dimnames")=List of 3

 .. attr(*, "dimnames")=List of 3
 .. ..$ tfd : chr [1:1501] "0" "0.01" "0.02" "0.03" ...
 .. ..$ cause: chr [1:3] "Surv" "Ins" "Dead"
```

Competing risks (cpr)

101 / 130

## Expected life time: using simulated objects

The areas between the lines (up to say 10 years) are **expected sojourn times**, that is:

- ▶ expected years alive without Ins
- ▶ expected years lost to death without Ins
- ▶ expected years after Ins, including years dead after Ins

Not all of direct relevance; actually only the first may be so.

They are available (with simulation-based confidence intervals) in the component of `cR`, `Stime` (Sojourn time).

Competing risks (cpr)

106 / 130

## Expected life time: using simulated objects

A relevant quantity would be the expected time alive without Ins during the first 5, 10 and 15 years:

```
> str(cR$time)
num [1:1501, 1:3, 1:3] 0 0.00998 0.01993 0.02984 0.03972 ...
- attr(*, "dimnames")=List of 3
..$ tfd : chr [1:1501] "0" "0.01" "0.02" "0.03" ...
..$ cause: chr [1:3] "Surv" "Ins" "Dead"
..$      : chr [1:3] "50%" "2.5%" "97.5%"
> round(cR$time[c("5","10","15"),"Surv"], 1)
tfd 50% 2.5% 97.5%
5   4.1 4.0 4.2
10  7.0 6.8 7.2
15  8.9 8.5 9.2
```

## A Lexis object

```
> L2 <- Lexis(entry = list(per = doBase,
+                          age = doBase - doBth,
+                          tfi = 0),
+            exit = list(per = doEnd),
+            exit.status = factor(deathCVD + !is.na(doDth),
+                                labels=c("Mic", "D(oth)", "D(CVD)")),
+            id = id,
+            data = steno2)
NOTE: entry.status has been set to "Mic" for all.
```

Explain the coding of `exit.status`.

## Multistate model

### simulation

Multistate models:  
Occurrence rates, cumulative risks, competing risks,  
state probabilities with multiple states and time scales with R and Epi::Lexis  
Baker HDI, 22-23 February 2023

<http://bendixcarstensen.com/AdvCoh/courses/Melb-2023>

## A Lexis object

```
> summary(L2, t = TRUE)
Transitions:
  To
From Mic D(oth) D(CVD) Records: Events: Risk time: Persons:
Mic 67 55 38 160 93 2416.59 160

Timescales:
per age tfi
" " " "
```

How many persons are there in the cohort?  
How many deaths are there in the cohort?  
How much follow-up time is there in the cohort?  
How many states are there in the model (so far)?

## Background: Steno 2 trial

- ▶ Clinical trial for diabetes ptt. with kidney disease (micro-albuminuria)
- ▶ 80 ptt. randomised to either of
  - ▶ Conventional treatment
  - ▶ Intensified multifactorial treatment
- ▶ 1993–2001
- ▶ follow-up till 2018

## Albuminuria status

```
> data(st2alb) ; head(st2alb, 3)
  id doTr state
1 1 1993-06-12 Mic
2 1 1995-05-13 Norm
3 1 2000-01-26 Mic
> cut2 <- rename(cal.yr(st2alb),
+               lex.id = id,
+               cut = doTr,
+               new.state = state)
> with(cut2, addmargins(table(table(lex.id))))
  1 2 3 4 5 Sum
4 25 40 46 41 156
```

What does this table mean?

## Steno 2 trial: goal

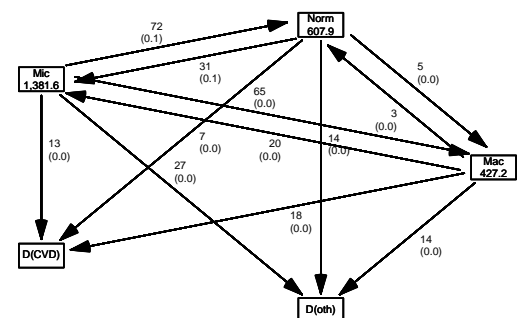

- ▶ Is there a treatment effect on:
  - ▶ CVD mortality
  - ▶ non-CVD mortality
- ▶ Does the treatment effect depend on:
  - ▶ Albuminuria state
- ▶ Quantification of treatment effect:
  - ▶ Rate-ratios
  - ▶ Life times
  - ▶ Changes in clinical parameters

## Albuminuria status as states

```

```

Explain all the numbers in the graph.

Describe the overall effect of albuminuria on the two mortality rates.

## How the split works

Same amount of follow-up

Same transitions

More intervals (5, resp. 37)

Different value of time scales between intervals

## Purpose of the split

- ▶ Assumption of constant rate in each interval
- ▶ All intervals are (shorter than) 0.5 years
- ▶ Magnitude of the rates depend on covariates:
  - ▶ fixed covariates
  - ▶ time scales
  - ▶ randomly varying covariates (not now)
- ▶ values of covariates differ between intervals
- ▶ each interval contributes to the (log-)likelihood for a specific rate from a given origin state (`lex.Cst`) to a given destination state (`lex.Xst`).
- ▶ —looks as the likelihood for a single Poisson observation

Multistate model (ssst)

126 / 130

`glm.Lexis` by default models all transitions to absorbing states, from states preceding these

```
> mX <- glm.Lexis(S4, ~ Ns(tfi, knots = seq( 0, 20, 5)) +  
+                   Ns(age, knots = seq(50, 80, 10)) +  
+                   lex.Cst)
```

NOTE:

Multiple transitions \*from\* state 'Mac', 'Mic', 'Norm' - are you sure?  
The analysis requested is effectively merging outcome states.  
You may want analyses using a \*stacked\* dataset - see ?stack.Lexis  
stats::glm Poisson analysis of Lexis object S4 with log link:  
Rates for transitions:  
Norm->D(CVD)  
Mic->D(CVD)  
Mac->D(CVD)  
Norm->D(oth)  
Mic->D(oth)  
Mac->D(oth)

Multistate model (ssst)

129 / 130

## Modeling the rate: Mic -> D(CVD)

```
> mr <- glm(cbind(lex.Xst == "D(CVD)" & lex.Cst != lex.Xst,  
+               lex.dur)  
+          ~ Ns(tfi, knots = seq( 0, 20, 5)) +  
+            Ns(age, knots = seq(50, 80, 10)),  
+          family = poisreg,  
+          data = subset(S4, lex.Cst == "Mic"))
```

... the same as:

```
> mp <- glm((lex.Xst == "D(CVD)" & lex.Cst != lex.Xst)  
+          ~ Ns(tfi, knots = seq( 0, 20, 5)) +  
+            Ns(age, knots = seq(50, 80, 10)),  
+          offset = log(lex.dur),  
+          family = poisson,  
+          data = subset(S4, lex.Cst == "Mic"))  
> summary(coef(mr) - coef(mp))  
      Min.   1st Qu.   Median     Mean   3rd Qu.    Max.     
-1.368e-12 -2.364e-13 -2.887e-14 -1.625e-13 -7.883e-15  6.839e-13
```

Multistate model (ssst)

127 / 130

Describe the model(s) in `mX` (look at the figure with the boxes)

- ▶ What rates are modeled ?
- ▶ How are they modeled (assumptions about shapes) ?
- ▶ What are the differences between the rates modeled?
- ▶ What would you rather do?

Multistate model (ssst)

130 / 130

## Modeling the rate: Mic -> D(CVD)

A convenient wrapper for `Lexis` objects simplifies things substantially:

```
> mL <- glm.Lexis(S4, ~ Ns(tfi, knots = seq( 0, 20, 5)) +  
+                   Ns(age, knots = seq(50, 80, 10)),  
+                   from = "Mic",  
+                   to = "D(CVD)")  
stats::glm Poisson analysis of Lexis object S4 with log link:  
Rates for the transition:  
Mic->D(CVD)  
> summary(coef(mr) - coef(mL))  
      Min. 1st Qu. Median   Mean 3rd Qu.    Max.     
      0      0      0      0      0      0  
> summary(coef(mp) - coef(mL))  
      Min.   1st Qu.   Median     Mean   3rd Qu.    Max.     
-6.839e-13  7.883e-15  2.887e-14  1.625e-13  2.364e-13  1.368e-12
```
